Abstract: Multiplier modules are common to many DSP applications. The fastest types of multipliers are parallel multipliers. Among these, the Array multiplier is the basic one. However, they suffer from more propagation delay. Hence, where regularity, high performance and low power are primary concerns, Booth multipliers tend to be the primary choice. Booth multipliers allow the operation on signed operands in 2's complement which are derived from array multipliers where each bit in a partial product line an encoding scheme is used to determine whether the bit is positive, negative or zero. The Modified Booth algorithm achieves a major performance improvement through radix-4 encoding. In this algorithm each partial product line operates on 2 bits at a time, thereby reducing the total number of the partial products. This is particularly true for operands using 16 bits or more.

Keywords: Array multiplier, parallel multiplier, propagation delay, VHDL, LUT, DSP block, utilization and twiddle f- actors.

Performance is recognized as a one of the critical parameter in digital system design field, especially in digital signal processing (DSP) applications. Fast multipliers are essential parts of digital signal processing systems. The speed of multiply operation is of great importance in DSP as well as in the general purpose processors today, especially since the media processing took off. In the past multiplication was generally implemented via a sequence of addition, Subtraction, and shift operations. Multiplication operation is the series of repeated additions, number to be added is the multiplicand and the number of times that it is added is the multiplier, and the result is the product. Each step of addition generates a partial product. In most computers, the operand usually contains the same number of bits. When the operands are interpreted as integers, the product is generally twice the length is determined by the performance of the multiplier because the multiplier is generally the slowest element in the system. In digit, serial multipliers have single digits consisting of several bits are operated on. These multipliers have moderate performance in both speed and area. However, existing digit serial multipliers have been plagued by complicated switching systems or irregularities in design. The parallel Multipliers provide high performance compared to serial multipliers and avoiding irregularities. In this paper, evaluating performance of 3 different parallel multipliers in terms of power, delay and area and find out which one is providing high performance of operands in order to preserve the information content. This repeated addition method that is suggested by the arithmetic definition is slow that it is almost always replaced by an algorithm that makes use of positional representation. It is possible to decompose multipliers into two parts. The first part is dedicated to the generation of partial products, and the second one collects and adds them. The basic multiplication principle is Two fold evaluation of partial products and accumulation of the shifted partial products.

1. MULTIPLIERS

Multipliers play an important role in today's digital signal processing and various other applications. With advances in technology, many researchers have tried and are trying to design multipliers which offer either of the following design targets – high speed, low power consumption, regularity of layout and hence less area or even combination of them in one multiplier thus making them suitable for various high speed, low power and compact VLSI implementation.

Characteristics of multiplier:

An efficient multiplier should have following characteristics:**Speed:** Multiplier should perform operation at high speed. **Area:** A multiplier should occupy less number of slices and LUTs. **Power:** Multiplier should consume less power.

Multiplication process has three main steps:

1. Partial product generation.
2. Partial product reduction.
3. Final addition.

Different types of multipliers:

Here we discuss different types of multipliers which are

1. Binary multiplier
2. Array multiplier
3. Booth multiplier
4. Modified booth multiplier

Binary multiplier:

A binary multiplier is an electronic hardware device used in digital electronics or a computer or other electronic device to perform rapid multiplication of two numbers in binary representation. It is built using binary adders. The rules for multiplication can be stated as

1. If the multiplier digit is 0 the product is also 0.
2. If the multiplier digit is 1 then the multiplicand is simply copied down and represents the product.
3. It should be capable of shifting left partial products.
4. It should be able to add all the partial products to give the products as sum of partial products.
5. It should be examine the sign bits. If they are alike the sign of the product will be a positive, if the sign bits are opposite product will be negative. The sign bit of the product stored with above criteria should be displayed along with the product.

Array multiplier:

It is well known due to its regular structure. Multiplier circuit is based on add and shift algorithm. Each partial product is generated by the multiplication of the multiplicand with one multiplier bit. The partial products are shifted according to their bit adders and then added.

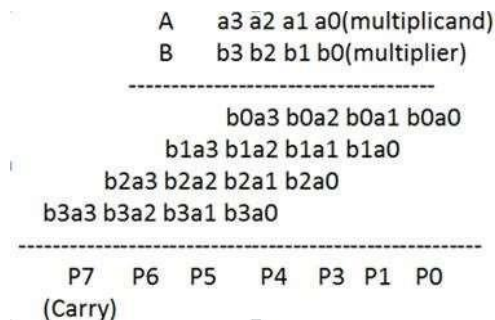

Fig3.1 Architecture of array multiplier boao is generated by using AND gate

For $m \times n$ Array multiplier Number of AND Gates are $m \times n$. The addition can be performed with normal carry propagate adder. $N-1$ adders are required where N is the multiplier length Numbers of Half Adders are n .

Numbers of Full Adders are $n(m-2)$ Total numbers of adders are $n(m-1)$

Booth multiplier:

Booth multiplication algorithm gives a procedure for multiplying binary integers in signed -2's complement representation. In booth multiplication process arithmetic shift and circular shift operations are performed.

Circular shift:

In combinational mathematics, a circular shift is the operation of rearranging the entries in a tuple, either by moving the final entry to the first position, while shifting all other entries to the next position, or by performing the inverse operation. A circular shift is a special kind of cyclic permutation, which in turn is a special kind of permutation. The results of repeatedly applying circular shifts to a given tuple are also called the circular shifts of the tuple. For example, repeatedly applying circular shifts to the four- tuple (a, b, c, d) successively gives.

- (d, a, b,c),
- (c, d, a,b),
- (b, c, d,a),
- (a, b, c, d) (the originalfour-tuple),and then the sequence repeats; this four-tuple therefore has four distinct circular shifts. However, not all n-tuples have n distinct circular shifts. For instance, the 4-tuple (a, b, a, b) only has 2 distinct circular shifts. In general the number of circular shifts of an n-tuple could be any divisor of n, depending on the entries of the tuple.

In computer programming a circular shift (or bitwise rotation) is a shift operator that shifts all bits of its operand. Unlike an arithmetic shift a circular shift does not preserve a number's sign bit or distinguish a number's

exponent from its mantissa. Unlike a logical shift, the vacant bit positions are not filled in with zeros but are filled in with the bits that are shifted out of the sequence. If the bit sequence 0001 0111 were subjected to a circular shift of one bit position

Fig3.2 Right circular shift operation Steps are for implementing the booth algorithm:

Let X and Y are two binary numbers and having m and n numbers of bits (m and n are equal) respectively.

Step 1: Making booth table: In booth table we will take four columns one column for multiplier second for previous first LSB of multiplier and other two (U and V) for partial product accumulator.

1. From two numbers, choose multiplier (X) and multiplicand (Y).
2. Take 2's complement of multiplicand(Y).
3. Load X_i value in the table.
4. Load 0 for X_{i-1} value.
5. Load 0 in U and V which will have product of X & Y at the end of the operation.
6. Make n rows for each cycle because we are multiplying m and n bit numbers.

Step2: Booth algorithm: Booth algorithm requires examination of the multiplier bits, and shifting of the partial product (P). Prior to the shifting, the multiplicand may be added to P, subtracted from the P, or left unchanged according to the following recoding rules:

Table3.2 Booth recoding table

	X_i	Operation to be performed
0	0	Shift only
1	1	Shift only
0	1	Add Y to U and shift

2. Take U & V together and shift arithmetic right shift which preserves the sign bit of 2's complement number. So, positive numbers and negative numbers remains positive and negative respectively.

3. Circularly right shift X because this will prevent us from using two registers for the X value. Repeat the same steps until n no. of cycles are completed. In the end we get the product of X and Y. Let us consider an example for Booth multiplication

The original version of the Booth algorithm (Radix-2) had two drawbacks. They are:

- (i) The number of add subtract operations and the number of shift operations becomes variable and becomes inconvenient in designing parallel multipliers.
- (ii) The algorithm becomes inefficient when there are isolated 1's. These problems are overcome by using modified Radix-4.

Modified booth multiplier:

It is a powerful algorithm for signed-number multiplication, which treats both positive and negative numbers uniformly. For the standard add-shift operation, each multiplier bit generates one multiple of the multiplicand to be added to the partial product. If the multiplier is very large, then a large number of multiplicands have to be added. In this case the delay of multiplier is determined mainly by the number of additions to be performed. If there is a way to reduce the number of the additions, the performance will get better.

Fig3.8 Radix-4 multiplication in dot notation

Table 3.3 below is used to convert a binary number to radix-4 number.

Initially, a 0 is placed to the right most bit of the multiplier. Then 3 bits of the multiplicand is recoded according to table below or according to the following equation: $Z_i = -2x_{i+1} + x_i + x_{i-1}$

Example: Multiplier is equal to 0 1 0 1 1 10 then a 0 is placed to the right most bit which gives 0 1 0 1 1 10 0 the 3 digits are selected at a time with overlapping left most bit as follows Table 3.3 Binary to Radix-4 conversion

B	Zn	Partial Product
000	0	0
001	1	1×Multiplicand
010	1	1×Multiplicand
011	2	2×Multiplicand
100	-2	-2×Multiplicand
101	-1	-1×Multiplicand
110	-1	-1×Multiplicand
111	0	0

table

For example, an unsigned number can be converted into a signed-digit number radix 4:

$$(10\ 01\ 11\ 01\ 10\ 10\ 11\ 10)_2 = (-2\ 2\ -1\ 2\ -1\ -1\ 0\ -2)_4$$

Here $-2 \times \text{multiplicand}$ is actually the 2s complement of the multiplicand with an equivalent left shift of one bit position. Also, $+2 \times \text{multiplicand}$ is the multiplicand shifted left one bit position which is equivalent to multiplying by 2. To enter $2 \times \text{multiplicand}$ into the adder, an $(n+1)$ -bit adder is required. In this case, the multiplicand is offset one bit to the left to enter into the adder while for the low-order multiplicand position a 0 is added. Each time the partial product is shifted two bit positions to the right and the sign is extended to the left.

During each add-shift cycle, different versions of the multiplicand are added to the new partial product depends on the equation derived from the bit-pair recoding table above.

3. FINAL RESULT

For comparison we have implemented different multipliers in terms of delay (ns), area and power. These Multipliers were modelled in VHDL and synthesized by using Xilinx design suite 14.4

PERFORMANCE COMPARISON OF ARRAY, BOOTH AND MODIFIED BOOTH MULTIPLIERS

	Array	Booth	Modified Booth
DELAY(ns)	23.856	30.798	7.818
POWER(mw)	0.081	0.014	0.014
BELLS(AREA)	123	458	22
I/O BUFFERS	32 (16+16)	33 (17+16)	27 (11+16)

The above table shows the performance comparison of different multipliers. In array Multiplier more area and high Power consumption. In comparison use of booth multiplier Occupies more area, low power consumption and speed is almost same as array multiplier.

The Modified Booth Multiplier is Best from the above multipliers because of area occupied is Less and more fastest multiplier in comparison to array and booth multipliers .it is consuming low poweralso.

CONCLUSION

We analyzed the area occupied, power consumed and the time delay consumed by different multipliers and found out best among them. After comparing all we came to a conclusion that Modified booth multiplier is best suited for high speed and low power applications.

FUTUREWORK

There are several future research directions are possible for further reduction of power and time delay consumption. One of the possible directions is radix higher-than-4 recoding. We have only considered radix-4 recoding as it is a simple and popular choice. Higher-radix recoding further reduces the number of PPs and thus has the potential of powersaving.
